February 1984
SSA Pub. No. 11-11537

FOREWORD

The development and analysis required for the adoption of economic assumptions used in pension valuations has been one of the most neglected areas in the actuarial field. This may be due in part to the lack of training among actuaries in the needed basic concepts of economics, or perhaps to the low level of importance that actuaries generally assign to this area. We believe, however, that this area cannot be neglected any longer. As actuaries become more aware of how closely the various instruments for income maintenance (especially Social Security and private pensions) are intertwined with the national economy, the need for actuarial projections and analyses in the economic field becomes more evident.

This Actuarial Study represents a first attempt by the Office of the Actuary to present to the public some of the methods that have been developed and some of the analyses that have been performed in the preparation of the economic assumptions used in the OASDI cost projections. There is still ample room for improvements and the Office will continue to strive for advancement in the future.

Comments from the readers are most welcomed and suggestions may be addressed to the undersigned or to one of the authors.

Francisco R. Bayo
Deputy Chief Actuary

A. BASIC CONCEPTS

This study summarizes the economic projections used for the analysis of the financial status of the Old-Age and Survivors Insurance and Disability Insurance Trust Funds appearing in the 1983 Annual Report of the Board of Trustees. The future income and outgo of the OASDI system will depend upon many economic factors, including labor force participation, unemployment, average earnings, and inflation. This study will discuss these factors and others in more detail than is given in the Trustees Report. Most of these other factors such as the Gross National Product (GNP) and productivity will be familiar to any reader with a basic background in modern economics. Some of these factors such as taxable payroll and covered workers will not be as familiar because they relate rather specifically to the OASDI system.

Although the precise value assumed for any parameter is somewhat arbitrary, the value must be chosen from a range that is considered reasonable in light of actual experience and its intended use. In this study we will show how the sets of assumptions used in the OASDI cost estimates were arrived at on the basis of consistency with historical experience, consistency with expected changes in the economy, and consistency with other assumptions within an alternative set and among alternative sets. In the case of assumptions that were chosen to test the range of reasonable cost estimates (i.e., alternatives I and III), we will show how cognizance was taken of the purpose of that test.

In a very basic sense, therefore, the economic assumptions that enter into the long-range OASDI cost estimates are not totally arbitrary; they are very much shaped by the myriad of economic and historical relationships as well as their intended use.

Because the precise forecasting of the behavior of economic factors is impossible, projections are shown in the Trustees Report on the basis of four sets of long-range assumptions, designated as alternatives I, II-A, II-B, and III. Alternative I is the most optimistic set of assumptions in terms of its net effect on the status of the trust funds, while alternative III is the most pessimistic. Alternatives II-A and II-B are referred to as intermediate sets of assumptions. Although they share the same demographic assumptions, their economic assumptions differ. The economic assumptions in alternative II-A, while not as optimistic as those in alternative I, are more optimistic than those in alternative II-B. Similarly, the economic assumptions in alternative II-B, while not as pessimistic as those in alternative III, are more pessimistic than those in alternative II-A.

The demographic assumptions used in this study are identical to those used to project the Social Security area population that was the basis for the 1983 Trustees Report. These population projections are presented in detail in Actuarial Study No. 88, "Social Security Area Population Projections, 1983," by John C. Wilkin, and are summarized in Tables 1.

An important result of the economic projections is the projected "effective taxable payroll." Long-range cost estimates for the OASDI system are normally expressed as a cost rate, which is defined as the system's expenditures as a percentage of the system's effective taxable payroll. The effective taxable payroll consists of the total earnings which are subject to Social Security taxation, including deemed wages based on military service. These total earnings are adjusted to reflect the lower effective tax rates (in comparison with the combined employee-employer rate) that apply to tips, multiple-employer "excess wages," and self-employment income through 1983. After these adjustments, the product of the effective taxable payroll and the combined employer-employee tax rate yields the accrued payroll tax liability for that given year. Therefore, the cost rates that are calculated using the above described effective taxable payroll, can be compared directly with the combined OASDI employee-employer tax rate scheduled in the law. The cost rate may be interpreted as that combined employer-employee tax rate that would be needed to exactly cover the expenditures. (Beginning in 1984, the OASDI Trust Funds will receive revenue from the income tax on OASDI benefits. Therefore, the OASDI tax rate needed to keep the OASDI system in actuarial balance will be slightly less than the cost rate.)

It is useful, when projecting effective taxable payroll, to think in terms of the "covered economy" rather than the total U.S. economy. The covered economy includes all wages and salaries and all self-employment income in employment covered by Social Security. Thus the covered economy is similar to the effective taxable payroll except that it includes all earnings above the maximum wage base taxable by Social Security (\$35,700 in 1983), and it does not include adjustments for variations in the applicable tax rates.

The covered economy overlaps significantly with the U.S. economy. However, some governments, nonprofit institutions prior to 1984, and other minor sections of the U.S. economy are not covered by Social Security. On the other hand, many workers in outlying areas ^{1/} and other U.S. citizens working for U.S. companies overseas are covered by Social Security but are not included in figures on the U.S. economy. Although many of the statistics that refer to the covered economy are not directly comparable to corresponding statistics for the U.S. economy we have placed our projections of the covered economy in the context of projections of the U.S. economy because this procedure has many advantages. For example, our projections can be more easily understood by economists and the general public. Also, much data are compiled on the U.S. economy and many projections of the U.S. economy prepared by other agencies can be used in our analysis. In addition, the interactions of the Social Security program with the U.S. economy can be analyzed more easily because of the consistency between the two projections.

^{1/} The term outlying areas refers to areas not normally considered to be part of the United States, such as Puerto Rico, the Virgin Islands, Guam, and American Samoa but which are covered by the Social Security system program.

Central to a long-range projection of the covered economy is a projection of the number of covered workers and a projection of their average covered earnings. The number of covered workers for a calendar year is defined as the number of workers who pay Social Security taxes during that year. Given an appropriate population projection, the basic assumptions necessary to project future workers are the labor force participation rates and the unemployment rates. Given the average earnings for a recent year, the basic assumptions necessary to project average earnings are the annual increases in the consumer price index (CPI) and in the real average wages.

Every month the Bureau of Labor Statistics (BLS) publishes the number of persons in the U.S. noninstitutionalized population 2/, in the total labor force, in the armed forces, in civilian employment, and unemployed. Before 1983 the published numbers on the U.S. population, the total labor force, and the armed forces included all of the armed forces whether they were resident in the U.S. or overseas, while after 1982 the similar numbers include only the armed forces resident in the U.S. From these data the BLS determines three rates: First, the total labor force participation rate, which is calculated as the total labor force divided by the U.S. population. Second, the civilian unemployment rate which is calculated as the number of unemployed divided by the civilian labor force, and which was the number most often quoted before 1983. Third, the total unemployment rate, which is calculated as the number of unemployed divided by the total labor force, and which is the number most often quoted after 1982. Annual average labor force participation rates and unemployment rates are normally calculated from the monthly figures. This study will only show the annual averages. All of these figures are published for all ages and sexes combined, as well as for specific age groups and each sex separately.

Because military employment, both in the U.S. and overseas, is covered by Social Security, the figures in this study (both past and projected) for the U.S. population, the total labor force, and the labor force participation rates will include all of the military. Also, the unemployment rate will refer to the total unemployment rate. The July 1 U.S. populations by age group and sex for 1947 through 1982 were estimated by the Bureau of the Census and published by the Bureau of Labor Statistics in Employment and Earnings. The U.S. populations for 1983 through 2060 were obtained by multiplying the Social Security Area population by age-sex specific factors, which were based on the historical relationship between the two populations. Table 2 shows the resulting estimates of the U.S. population in the past and as projected by alternative.

Every year, the Social Security Administration gathers data on the number of covered workers and on their average earnings. The coverage rates--which are defined as the ratio of covered workers during a year to the

2/ In this study the term "U.S. population" will refer to the noninstitutionalized population of the U.S., rather than the resident U.S. population that is most often quoted by the Bureau of the Census.

mid-year Social Security Area population--can be calculated from these data. These rates are calculated by age group and sex, and are usually expressed in percentages.

Although there are many differences in concept between covered worker rates and labor force participation rates, their numerical levels for each age-sex group are fairly close. As shown in Tables 10 and 11, the covered worker rates tend to be higher than the corresponding labor force participation rates for low values, while the reverse is true for high values. The labor force participation rate differs from the covered worker rate for several reasons: One reason is that some workers in the labor force are not covered workers (i.e., they work in noncovered employment). Another reason is that the denominators used to calculate the rates are different (i.e., the U.S. population versus the Social Security Area population). Both of these factors tend to result in a covered worker rate that is lower than the corresponding labor force participation rate by about the same percent for all age-sex groups. On the other hand, some workers are in covered employment and are not in the labor force (e.g., a covered worker in Puerto Rico). Also, a worker is counted as covered for the whole year if he works in covered employment any time during that year, whereas the same worker must be in the labor force in each month of the year to be counted as in the labor force the whole year. These differences tend to result in a covered worker rate that is higher than the corresponding labor force participation rate. This last difference is much larger for age-sex groups with low rates than age-sex groups with high rates.

The cyclical nature of economic growth makes difficult the detection of trends in economic variables. During economic expansion, increases in the CPI and average wages accelerate, while labor force participation increases and unemployment decreases. During economic contraction, the opposite is true. A useful concept for analyzing past trends and for making projections is that of the economy's potential output in constant dollars under normal circumstances. This concept, called potential real Gross National Product, is the output in constant dollars that the economy could produce with the existing technology under assumed conditions of high but sustainable use of the factors of production--labor, capital, and natural resources. The Council of Economic Advisers has estimated potential real GNP for past years based on (1) an overall civilian unemployment rate that takes into account the age distribution of the labor force and has changed gradually from 4.0 percent in 1955 to 4.9 percent in 1976, and (2) a manufacturing capacity utilization index of 86 percent as calculated by the Department of Commerce. With these assumptions potential real GNP increases in accordance with the size of the labor force and of capital and thus grows smoothly through time. Because this smooth trend is easier to project, it is of fundamental importance in the development of the economic projections used in the OASDI Trustees Report. In our projection method, increases in capital are implicit in assumed increases in productivity.

Use of potential real GNP rather than the actual real GNP as a fundamental concept facilitates consistency of long-range projections from one year's Trustees Report to the next year's regardless of the change in the economy's position in the business cycle between the two years. Our projection of GNP is based on assumed annual rates of increase of selected economic parameters. Applying these rates of increase to a base year that follows an erratic path would result in a shift in the level of the projection into the long-range future, even if there were no change in our assumed rates of increase. By applying rates of increase to values of economic parameters that are based on the smooth potential real GNP series, a significant change in the projected level of the economic parameters will only occur if we change our assumptions.

B. ASSUMPTIONS

Any creditable economic projection will begin with an analysis of past experience. When setting long-range assumptions, this analysis must encompass a reasonably long period of time. The values of economic parameters often fluctuate significantly from one year to the next as the economy moves through a business cycle. In addition, these cycles often take place within trends that include several cycles. The economic experience during these trends can be significantly better or worse than the long-range average. We have analyzed the experience of selected economic parameters back until at least the early 1950's so as to include favorable as well as unfavorable trends. Thus, although recent experience is important in establishing a starting point and the current trend for our projections, it is not allowed to influence too heavily our choice of ultimate values.

The experience of the 1950's and 1960's provides an example of a period when the economy operated very favorably through several cycles. Inflation was low, averaging only 2.4 percent per year, while productivity grew rapidly, averaging 2.8 percent per year. On the other hand, the experience of the last 10 years has been very unfavorable. Inflation averaged 8.7 percent per year from 1972 to 1982, while productivity increased at an average annual rate of only 0.9 percent. Our long-range trend projections take all of this experience into account.

1. Consumer Price Index

The Consumer Price Index (CPI) is a measure of the average change in prices over time in a fixed market basket of goods and services that people buy for day-to-day living. It is published monthly by the Bureau of Labor Statistics (BLS), and it has been published since 1913. In 1978, BLS began publishing CPI's for two population groups: (1) a new CPI for all Urban Consumers (CPI-U), which covers approximately 80 percent of the total noninstitutionalized civilian population; and (2) a revised CPI for Urban Wage Earners and Clerical Workers (CPI-W), which represents about half the population covered by the CPI-U. Although the CPI-U is the index most often quoted by BLS, the CPI-W is consistent with the CPI as it existed in 1973 when the Social Security automatic benefit adjustment provisions were enacted and it is the index currently used to index Social Security benefits. Therefore, the CPI-W is the index projected in this study.

Beginning with January 1983, BLS changed the way homeowner costs are measured in the CPI-U to rental equivalence. The rental equivalence approach calculates homeowner costs on the basis of the rent that owners would have to pay to rent the homes they own. The old method calculated homeowners costs as home purchase, mortgage interest costs, and property taxes, insurance, and maintenance and repair. The weights for home purchase and mortgage interest represented only persons who purchased a home in the base period. The CPI-W will be changed for January 1985. Although from the late 1960's through 1981, the rental equivalence method generally has risen more slowly than the old method, the opposite has been true more recently. Over the long-range future there is no reason to expect one measure to increase faster than the other.

Since 1913 the CPI has increased at an annual average rate of 3.4 percent. The annual increases have fluctuated between +17.4 percent in 1918 and -10.7 percent in 1921, making the detection and projection of trends difficult. In order to obtain a smoother time series, average annual increases over selected intervals were calculated. These increases in the CPI are shown in Table 3.

Table 3 shows that the 10-year moving average does a good job of smoothing out the fluctuations of the annual increases. This averaging also reveals that there has been a cyclical pattern of about 30 years duration. Thus, the 30-year moving average is a good choice in trying to discern whether or not there has been a long-range trend in the CPI. This average shows a steady upward trend from 0.61 percent for the 30 years ending in 1950 to 4.39 percent for the 30 years ending in 1982.

Of course, a numerical review of historical figures is only the first step in making projections for the future. We must look behind these trends and try to determine the underlying factors that are influencing them. This is particularly the case when the factors are expected to vary in the future. For inflation, these underlying factors are mixed, some pointing to an upward trend and others pointing to a downward trend.

On the upward side: Past experience has shown that restrictive fiscal and monetary policies are effective tools (although not perfect tools) for fighting inflation. Because these restrictive policies also result in an increase in unemployment, however, they are applied only when the effects of inflation have become worse than the effects of increased unemployment. During "demand-pull" inflation, which occurs when demand exceeds the productive capacity of the economy, and when unemployment is low, restrictive policies can be applied relatively painlessly while effectively lowering inflation. These policies are less effective on "cost-push" inflation, as was experienced during the 1970's, when unemployment is already high. Thus, we no longer believe that inflation can always be easily controlled by fiscal and monetary policy.

Cost-push inflation can sometimes be started by events outside of our own economy. For example, the effectiveness of the OPEC oil cartel in raising oil prices during the 1970's shows that raw material prices could have a significant, and uncontrollable, effect on inflation at some unforeseen time in the future.

Of course, the purpose of government spending is to provide the public with needed goods and services and not just to manipulate aggregate demand in the economy so as to produce full employment and low inflation. Thus, the effectiveness of fiscal policy will always be tempered by the difficulty of cutting government programs that have a direct effect on some constituency and the need to spend every dollar wisely.

On the downward side: With each new economic experiment and economic cycle, the practical effects of economic theory become better understood. The powerful effects of a tight monetary policy is one recent example. Thus it has been shown that a restrictive enough monetary policy can reduce cost-push inflation even while fiscal policy is expansionary. However, the

slow down in inflation was still accompanied by a significant rise in unemployment and a decline in real GNP. Low inflation has the long-term advantage of lower interest rates and more savings which in turn lead to more investment and greater productivity. As these long-term advantages become better known to the general public, restrictive policies become more acceptable. Also, although future shocks to inflation similar to the two oil price shocks of the 1970's are certainly possible over the next 75-years, it is unlikely that they will occur with a magnitude and frequency that will influence average inflation over the next 75 years as they have influenced inflation experience over the last decade.

Because the future course of inflation is so uncertain and because the long-term historical experience has been fairly stable despite significant fluctuations in short term inflation, we have chosen ultimate long-range inflation rates which are not too different from the long-term average historical experience. The rates of 2.0 percent, 3.0 percent, 4.0 percent, and 5.0 percent were chosen for alternatives I, II-A, II-B, and III, respectively. The past and projected annual increases in the CPI are shown in Table 4.

2. Average Real Wages

Two different analyses were used to aid in the projection of the annual increases in average real wages. The first analysis examined directly the annual experience on the increase in average real wages. The second analysis examined experience on average real wages, productivity, and the linkages between the two. Although our projection method calls for the assumed growth in average real earnings, our main analysis has been on real wages. The difference between these two is that figures on earnings include self-employment income in addition to wages and salaries. We believe that a better analysis of the trend in real earnings can be made by excluding self-employment income, because the historical data on self-employment income are available only after many years of delay, because they are less reliable than the data on wages, and because they have been affected significantly several times since the early 1950's by changes in the coverage of the social security system. In addition, self-employment earnings are becoming less significant; they were only 3.9 percent of GNP in 1982 versus 13.1 percent in 1951. In the past, average self-employment earnings have increased more slowly than average wages, although average self-employment earnings are still higher than average wages.

Table 5 shows the average annual wages of covered workers indexed to 1967 by the CPI, along with the average annual increase over selected intervals. The annual increase in average real wages has fluctuated between -4.2 percent in 1980 and a +5.6 percent in 1953. Just as with the CPI, it is easier to detect trends by combining several years of data. The moving averages shown in Table 5 reveal that the general trend since the mid-1960's has been downward. Few analysts believe that the future trend will be to continue monotonically downward, or even to level off at the current low level, most believe that fluctuations can be expected in the future.

There are many factors that have affected average real wages in the past that can be expected to affect average real wages in the future. It is difficult to enumerate all of these factors and even more difficult to quantify their effects.

We have attempted to quantify the effects of the changing age-sex composition of covered workers. Because average wages vary by age and sex, a change in the composition of the workforce affects the average for all workers combined. Table 6 shows the annual increases in average real wages, age-sex adjusted according to the age-sex distribution of the 1970 covered workers. Thus, Table 6 is a modification of Table 5 that permits us to quantify the effects that the changing age-sex composition of covered workers has had on average real wages for all workers combined. The average real wages for each specific age-sex group are the same in Table 6 as in Table 5, but for each year the weighting of each age-sex group in Table 6 is based on the distribution of covered workers in 1970, while the weighting in Table 5 is based on the actual distribution of the specified year. The analysis shows that since 1951, the changing composition of the workforce has had a dampening effect on increases in average real wages. The average annual increase over the 30-year period 1952 to 1982 was 1.12 percent, but it was 1.33 percent on the adjusted basis. It also shows that this demographic effect on average real wages has become much less significant recently. Our analysis based on the expected future age-sex distribution of covered workers shows that there will be a very favorable trend from now until 1995, adding roughly 0.5 percent to the annual increase in average real wages and that after 1995, the demographic effects should be of little consequence.

This demographic labor force composition effect (that seems to have depressed the growth in average real wages in the past but, which will likely aid in their growth in the near future) is the result of the increasing labor force participation of women and the movement through the various working ages of the large baby boom generation. When the labor force participation of women levels off, their depressing effect on annual increases in average real wages will diminish. Average real wages have also been depressed while the baby boom generation was entering the labor force, but they will be enhanced when the baby boom generation enters their prime earning years.

Because, over a long period of time, increases in average real wages are only possible if productivity increases, our second analysis of annual increases in average real wages is based on the analysis the of productivity of covered workers and of the linkages between their productivity and their average real wages. The relationship between productivity (production per hour paid) and average wages per year can be summarized in the following formula:

$$\frac{\text{Production}}{\text{Hour}} \cdot \frac{\text{Compensation}}{\text{Production}} \cdot \frac{\text{Wages}}{\text{Compensation}} \cdot \frac{\text{Hours}}{\text{Week}} \cdot \frac{\text{Weeks}}{\text{Year}} = \frac{\text{Wages}}{\text{Year}}$$

From this equation additional insight into increases in average real wages can be obtained by analyzing increases in productivity and changes over time in each of the above linkages. Because the data necessary to analyze the factors on the left side of this equation are not available for the covered economy, we relied upon data for the U.S. economy. The significant overlap between these two economies should prevent any major statistical discrepancies in this analysis. Table 7 summarizes the average annual changes in each of these factors over the period 1952 to 1982.

Table 7 shows that the decline in the growth rate of average real wages has been the result of declines in the growth of productivity and some declines in the linkages. However, one linkage whose effect has been in the direction of an increase in average real wages is the ratio of compensation to production. This ratio is calculated by dividing the total employee compensation in the U.S. economy by the Gross National Product. This ratio can be thought of as a weighted average of the ratio of compensation to production for three sectors of the economy; self-employed, private non-self-employed, and government. The ratio for the self-employed sector is by definition equal to 0, and for the government sector is by definition equal to 1. Over the last 30 years the self-employment sector has dropped from 13 percent of GNP to 4 percent, while the government sector has increased from 9 percent to 12 percent. Both of these trends have resulted in an increase in the ratio of compensation to production, and explain the increase in this ratio over the last 30 years. Thus, the ratio of private employee compensation to private nonself-employed GNP has remained stable, changing only slightly from 58.5 percent in 1951 to 58.0 percent in 1982. We are assuming no future change in this ratio.

The second linkage is the ratio of wages to compensation, which has had a depressing effect on the growth in average real wages. Both wages and compensation are items in the National Income and Product Accounts (they are technically called "wages and salaries" and "compensation of employees," respectively) and are published in the Survey of Current Business by the Department of Commerce. Total employee compensation includes fringe benefits in addition to wages and salaries. The decline in the ratio of wages to compensation is the result of fringe benefits increasing at a faster rate than wages. Since fringe benefits offer both employers and employees many advantages it can be expected that they will continue to grow faster than wages.

In many cases, fringe benefits are more desirable to employees than wages, because fringe benefits are often afforded better tax treatment and because they often provide, on a group basis, benefits that are either unavailable or much more expensive on an individual basis. Fringe benefits can also help employers to compete for new employees and to retain experienced ones. Therefore, more workers can be expected to be covered by fringe benefit plans in the future, and those that are covered can expect an expansion in the types of benefits provided. In addition, the costs of many types of benefits, such as health insurance and pension plans, are rising faster than wages even without a liberalization in plan provisions. Because of

all of these reasons, we believe that there is still much potential for future faster growth in fringe benefits relative to wages.^{3/} The assumed ultimate annual rate of decline in this ratio is 0.1 percent, 0.2 percent, 0.3 percent, and 0.4 percent for alternatives I, II-A, II-B, and III, respectively.

The third linkage is the hours paid per week, which has also had a depressing effect on the growth in average real wages. In the analysis of the average number of hours paid per week we used the figures published by BLS in Employment and Earnings for the total private nonagricultural sector of the U.S. economy. The decline in the number of hours paid per week has been fairly steady over the last 30 years. Some of the factors contributing to this decline are the relative increase of young workers and female workers in the labor force, (both of whom work fewer hours than the average), the relative increase in the importance of service industries versus manufacturing, and a desire by labor to work fewer hours (particularly when their average real wages are increasing). We believe that this decline in the average number of hours paid per week will continue into the future, but at a slightly slower pace than in the past. We are assuming an ultimate annual rate of decline of 0.1, 0.2, 0.3, and 0.4 percent for alternatives I, II-A, II-B, and III, respectively.

Although the increases in average real wages were smaller during the 1960's than the 1950's, increases in productivity were actually higher in the 1960's. Then, from 1972 to 1982 increases in productivity dropped significantly, averaging only 0.89 percent per year. This drop in productivity gains can be partially explained by the effect of the changing age-sex distribution of the workforce, the rapid growth of the labor force (which depressed the capital to labor ratio), the economic shock of the large increases in oil prices, and the acceleration in government regulation in areas of health, safety, and the environment. Because none of these factors are likely to have an increasingly depressing effect on productivity, we believe that productivity is likely to increase in the future more rapidly than it has over the last 10 years. Over the long-range, however, it is unlikely that increases at rates comparable to those of the 1950's and 1960's could be obtained. The economy cannot be assumed to operate indefinitely under an ideal set of circumstances. Even though the particular disruptions of the 1970's are unlikely to reappear, other unforeseen disruptions can be expected to occur. In line with the long-term historical experience the ultimate assumptions for the average annual increase in productivity are 2.7, 2.4, 2.1, and 1.8 percent for alternatives I, II-A, II-B, and III respectively.

The fourth and last linkage is the average number of weeks paid per year per covered worker. Because this statistic is not measured directly the past values were calculated as a residual and, therefore, it also includes any statistical discrepancies among the other figures. This ratio has declined at an average annual rate of 0.42 percent over the last 30 years,

^{3/} See, Wilkin, Gresch, and Glanz, "Growth in Fringe Benefits", Actuarial Note 113, Social Security Administration, Baltimore, MD, June 1982.

thus depressing the growth of average annual real wages. Some of the decline can be explained by the increasing proportion of covered workers being comprised of young workers and female workers, who are more likely to work a partial year. As was mentioned in the previous section, this trend has already begun to taper off and reverse. Over the long-range period we are assuming that this ratio will stop its decline and level off.

When analyzing the covered economy, this linkage must be used in a manner consistent with the concept of the number of covered workers for a year, i.e., the number of workers who were paid wages in covered employment sometime during that calendar year. When used this way, this linkage represents the average number of weeks paid per year by the covered workers in that year. Thus, it is a nontrivial linkage. When analyzing the U.S. economy, this linkage must be used in a manner consistent with the concept of the number of workers in the labor force for a year, i.e. the average number of workers in the labor force throughout that calendar year. When used this way, this linkage is by definition 52 weeks per year.

Based on the analysis that is briefly described above we assumed ultimate annual growth rates in average real earnings of 2.5, 2.0, 1.5, and 1.0 percent for alternatives I, II-A, II-B, and III, respectively. These assumptions along with those on productivity and the linkages are summarized in Table 7.

For simplicity, in the Trustees Report we use the concept of the real wage differential rather than the annual increase in average real wages. The annual increases in average real wages are calculated by first indexing average wages to 1967 by the CPI, and then calculating compound annual rates of change. The real wage differential, on the other hand, is calculated as the annual compound rate of increase in average nominal wages minus the annual compound rate of increase in the CPI, expressed as a percent. Past and projected real wage differentials are shown in Table 8. A real wage differential of 1.5 combined with an annual increase in the CPI of 4.0 percent results in an increase in average nominal wages of 5.5 percent, which is equivalent to an annual compound rate of increase in the average real wage of 1.44 percent combined with a similar annual increase in CPI of 4.0 percent.

3. Unemployment Rate

Since 1947 the unemployment rate has fluctuated between a low of 2.8 percent in 1953 and 9.5 percent in 1982, as shown in Table 9. Because the unemployment rate fluctuates widely with the business cycle, it is useful to average several years of data together. Table 9 also shows the average unemployment rate over selected intervals. The 5-year average has fluctuated between 3.6 percent and 7.1 percent. However, the long-range trend has recently turned upward, as shown by the 15-year moving average which has risen from 5.0 percent in 1975 to 6.1 percent in 1982.

The recent high unemployment rates are the result in part of the changing age-sex composition of the labor force, the restructuring of the labor force to take advantage of improvements in technology, the extension of unemployment benefits, and the recent poor performance of the economy.

The increase during the 1970's of the proportion of women and youth in the labor force has caused some of the increase in the unemployment rate because women and youth experience higher levels of unemployment than adult males. While the actual 15-year average unemployment rate rose 1.4 percent from 4.7 to 6.1 percent from 1970 to 1982, the age-sex adjusted 15-year average rate rose only 1.0 percent from 5.1 to 6.1 percent.

Many of the technological advances made over the past decade have resulted in new equipment and methods in the office and in the factory. Office automation and factory robotization has eliminated many blue collar jobs while creating many other jobs that require a higher level of technological training. This has made it necessary for the present labor force to retrain for new careers, leading to higher unemployment rates during the transition. Of course, the permanent loss of certain occupations and the creation of new ones is always a part of our dynamic economy, but the recent losses in such industries as automobiles and steel and gains in such industries as computers and telecommunications have been at a much increased rate.

For some members of the labor force, the extension of unemployment benefits has served as a disincentive to seeking new employment. As mentioned before, the poor performance of the economy during the 1970's must be viewed as atypical, the result of such factors as the oil price shocks, food price shocks, increased regulation, high inflation and rapid growth of the labor force. Although the future will not be free of periods of poor economic performance, on average future experience should be better than that of the 1970's.

After considering all of these factors, we chose average ultimate age-sex adjusted unemployment rates of 4.0, 5.0, 5.5, and 6.5 percent for alternatives I, II-A, II-B, and III, respectively. The age-sex specific rates were determined based on their past relationship with the age-sex adjusted rate. Past and projected unemployment rates by age group and sex are shown in Tables 9.

4. Labor Force Participation Rates

As shown in Table 10C, from 1947 to 1982 the age-adjusted female labor force participation rate rose from 30.1 percent to 52.8 percent, a 75 percent increase. Because of this substantial increase, the age-sex-adjusted total labor force participation rate rose 15 percent from 56.2 percent to 64.4 percent during the 1947-82 period, even while the age-adjusted labor force participation rate of males was dropping from 84.6 percent to 76.9 percent.

The decision to participate in the labor force depends upon many factors, including a person's marital status, the presence of a disabling condition, the state of the economy, the presence of children in the family, and for older workers the availability and level of retirement benefits. We have compared the trend in the labor force participation rate for each age group and sex separately with the trend in each of these factors.

Since 1947 the labor force participation of women has increased substantially at all ages except for ages 65 and over, with the largest increases between ages 25 and 50. This increase has coincided with a decrease in the percentage of women who are married and a decrease in the number of children per woman. Except in alternative III, which assumes that fertility rates will continue to decrease, both the percentage of women married and the number of children per woman are projected either to stay at about current levels or to increase. Therefore, any contribution that these factors may have made to recent increases in the labor force participation rates of women cannot be expected to continue in the future. Their effect may actually be reversed. However, we believe that these factors have only partially contributed to the recent increases and that such increases reflect fundamental changes in our society, especially with regard to the opportunities, rights, perceived abilities, and responsibilities of women. We expect this underlying trend to continue and have assumed that it will result in the labor force participation rates of women under age 55 being roughly 10 percentage points higher, by the year 2005, than they would be if only changes in fertility and marital status were considered. Because recent increases in the labor force participation rates of the relatively young cohorts of women are likely to result in increased participation during the remainder of their working lifetimes, we believe that as these cohorts age future increases in the labor force participation rates of relatively older women will be slightly higher than those of the younger women.

In 1982 the labor force participation rate of men in their 20's was about the same as it was in 1947, although the rate generally increased early in this period and has been dropping recently. For all age groups 30 or over the rates were lower in 1982 than in 1947 with the largest decreases at the highest ages. The rates dropped 1.1 percentage points from 96.7 to 95.6 for those aged 30-34, 4.8 percentage points from 94.5 to 89.7 for those aged 50-54, and 35.3 percentage points from 62.2 to 26.9 for those aged 65-69. The small decreases during the prime working ages may be the result of the increases in the participation rates of females and increased unemployment insurance, while the significant decreases at the older ages are largely the result of the trend towards earlier retirement. This latter trend, which is also displayed by the participation rates of older females, may be the result of more prevalent and richer pension plans (including Social Security) and increased personal savings.

In our projection for the future, we are not assuming any underlying trend in the participation rates of males between ages 25 and 50. For males above age 50 and for females above age 65, we are assuming that the recent

trend towards earlier retirement will result in the participation rates being a few percentage points lower in the future than they otherwise would be. Of course, we are assuming an increase in the labor force participation of workers aged 62 and over beginning in the year 2000 because of the provision in P.L. 98-21 that raises the normal retirement age from 65 to 67 during the period 2000 to 2022.

For both males and females, we are assuming that the labor force participation rates of persons under age 20 will increase significantly as the number of teenagers decreases rapidly. Also, for all ages and both sexes, we are assuming an increase in labor force participation as the economy moves from the 9.5 percent unemployment rate in 1982 towards fuller employment.

The past and projected labor force participation rates by age group, sex, and alternative are shown in Tables 10. The total rate for all persons 16 and over moves from 64.3 percent in 1982 to 66.8 percent, 61.3 percent, 59.9 percent, and 51.2 percent in 2060 in alternatives I, II-A, II-B, and III, respectively. Except for alternative I, the total rate decreases even though large increases are assumed for most of the age specific rates of women. This results from the large increase in the proportion of the population that is over age 65 where the rates are low, and occurs even with the increased participation rates that result from the scheduled increase in the normal retirement age. On an age-sex adjusted basis, the rates increase significantly under all four alternatives from 64.4 percent in 1982 to 71.3 percent, 70.0 percent, 68.5 percent, and 67.4 percent in 2060 for alternatives I, II-A, II-B, and III, respectively.

C. METHODS

1. Covered Worker Rates

The projected covered worker rates for each year were calculated by age and sex with modified regression equations on the labor force participation rates and the age-sex-adjusted unemployment rate. The regression analyses used data that started in the mid-to-late 1950's because significant changes in OASDI coverage of employment were enacted in 1954 and 1955 and these changed the relationship between labor force participation rates and coverage rates. The specific starting year of the regression analysis was chosen for each age group and sex separately, based on when the relationships between the labor force participation rates and the covered worker rates appeared to become stable after the changes in the law. The regression analyses ended with data for the year 1978, the last year for which data on covered workers were available. In the regression analyses, more weight was given to the more recent years to more accurately reflect the effect of several minor changes in coverage that have occurred since 1955 and to provide for a smoother junction between historical rates and projected rates. The data for the starting year were given one-half the weight of the final year of 1978.

It was necessary to modify the regression equations to produce reasonable coverage rates from labor force participation rates that were projected to increase significantly above the historical values used in the regression analysis. The modification was designed so that as the labor force participation rates approached 100 percent the coverage rates would approach a value slightly less than 100 percent. Coverage rates were not allowed to reach 100 percent even theoretically because, even if all the population were in the labor force not everyone in the labor force is employed and not everyone who is employed is covered. Tables 11A through 11G show the past and projected covered worker rates by age, sex, and alternative.

2. Labor Force and Covered Workers

The average number of workers in the labor force (including the military) for each year was determined by multiplying the age-sex specific labor force participation rates by the U.S. population. The past and projected labor force by age group, sex, and alternative is shown in Tables 12A through 12G.

The number of covered workers for each year was determined by multiplying the age-sex specific covered worker rates by the Social Security Area population. Tables 13A through 13G show the past and projected number of covered workers by age group, sex, and alternative.

3. Ratio of Effective Taxable Payroll to Gross National Product

An important characteristic of the economic projections presented in this study is that there is consistency between the U.S. economy and the covered economy, and in particular, there is consistency between GNP and effective taxable payroll. If this consistency is to be obtained, the determination of the ratio of effective taxable payroll to GNP must be given a high level of importance in the methods used. Once this ratio is obtained one can start by projecting GNP and then determine effective taxable payroll, or start by projecting effective taxable payroll and then determine GNP. Our projection methods use both approaches but in such a manner that either GNP or effective taxable payroll could be viewed as the fundamental value of the projection by being determined from more basic factors. In general, in our methods, GNP is the more basic concept for the first 10 years of the projection, 1983-1992, and effective taxable payroll is the more basic concept for the long-range period, 1993-2057. For the remainder of this paper effective taxable payroll will be referred to simply as "payroll."

As shown in Table 14A, since 1951, the ratio of payroll to GNP has fluctuated between 35 percent and 44 percent. It is difficult to determine the reasons for these fluctuations, and thus to form a basis for projecting into the future, without taking several intermediate steps in going from payroll to GNP. The ratios between successive intermediate steps are chosen to produce linkages which have exhibited smooth and/or explainable trends, thus making the projection easier to understand. The linkages between GNP and payroll have many similarities to the linkages between productivity and real wages.

The analysis of the payroll is broken into two major pieces: the effective taxable wages and the effective taxable self-employment income. In the analysis of the effective taxable wages it is useful to start with total employee compensation--that is, the employees' share of the total value of production in the U.S. The ratio of employee compensation to GNP rose from 55 percent in 1951 to 58 percent in 1960, and to 60.7 percent in 1969. Since 1969, this ratio has generally remained between 60 and 61 percent. This is the ratio whose average annual rate of change was analyzed in the real wage section as compensation per production. As previously stated, the past growth in this ratio appears to be the result of shifts in the relative sizes of various sectors of the economy, and we do not anticipate any long-range trend away from current experience in this ratio. Therefore, we are projecting this ratio to remain at 60.0 percent during the long-range projection period for all four alternatives.

Because only the wage portion of employee compensation is subject to taxation, it is useful to analyze the ratio of wages to compensation. This ratio has declined steadily over the last 30-years at an average annual rate of 0.4 percent. This means that other forms of compensation, generally referred to as fringe benefits, have been growing faster than wages. Of course, for our purpose the term "fringe benefits" refers only

to that portion of total compensation not subject to Social Security taxes such as group insurance and pension plan contributions. Cash items, such as vacation pay, which are treated as a continuation of wages and are taxed, are not included in fringe benefits. Again, the average annual rates of change in this ratio were analyzed in the real wage section, and the ultimate annual rate of decline was assumed to be 0.1 percent, 0.2 percent, 0.3 percent, and 0.4 percent for alternatives I, II-A, II-B, and III, respectively.

Not all wages in the U.S. economy are paid for employment that is covered by Social Security, and vice versa. Therefore, it is useful to analyze the ratio of covered wages to total wages. This ratio is highly dependent upon the types of employment that the Social Security Act specifies as being covered. This ratio rose from 77 percent in 1951 to 87 percent in 1960 as a result of the expanded coverage provided by several laws during the 1950's. The most significant new groups were farm and domestic workers and the armed forces. Coverage also expanded several times during the 1960's and 1970's although to much less significant types of employment, so that the ratio of covered wages to total wages increased to 88.1 percent in 1970 and to 90.8 percent in 1982. These increases have occurred even while many State and local governments and nonprofit institutions have dropped their coverage under Social Security. These past increases in coverage explain much of the past increases in the ratio of payroll to GNP.

Future increases in the ratio of covered wages to total wages can be expected as a result of P.L. 98-21, which was passed on April 20, 1983. This law makes coverage of all employment in nonprofit institutions and of all newly hired civilian federal employees mandatory after 1983. In addition, it prohibits State and local governments from withdrawing their coverage in the future. We are assuming that covered wages will increase to over 95 percent of total wages just after the turn of the century under all four alternatives.

Covered wages above the contribution and benefit base are not taxed (except for the employer tax on excess multiple-employer wages). Therefore, it is useful to analyze the ratio of taxable wages to covered wages. In the past, when there were only infrequent ad hoc increases in the wage base, this ratio tended to drift downward as wages increased and then to spike up in the year of a wage base increase. Since the wage base has been indexed to automatically increase with average wages this ratio has become more stable. However, recent ad hoc increases which were greater than the automatic increases that would have occurred, have pushed this ratio to 91 percent in 1982. The automatic provisions of present law should keep this ratio fairly stable in the future. Therefore, the ratio of taxable wages to covered wages is assumed to remain ultimately at just over 91 percent, varying only slightly by alternative.

Taxable wages include all wages subject to the FICA tax. In general, employers and employees are each taxed on these wages. However, there are two exceptions. Only the employee tax is applied to tips representing renumeration above the minimum wage level and only the employer tax is

applied to "multiple-employer excess wages". Multiple-employer excess wages occur when an employee receives wages from more than one employer during a calendar year and the combined wages exceed the maximum taxable wage base. During the year each employer will remit taxes for both itself and the employee up to the maximum independently of any wages paid to the employee by another employer. At the end of the year, the employee will receive a refund on any taxes remitted for him above the maximum, while the employers receive no such refund. Taxable wages on which the employee tax is applied are referred to as employee taxable wages. These include all tips and exclude multiple-employer excess wages. Taxable wages on which the employer tax is applied are referred to as employer taxable wages. These include multiple-employer excess wages and exclude tips representing renumeration above the minimum wage level. The ratios of employee taxable wages to taxable wages and employer taxable wages to taxable wages are just under 1.0. The employer taxable wages are higher than the employee taxable wages since the "excess wages" at the current wage base are higher than the tips. Effective taxable wages are the average of the employee taxable wages and the employer taxable wages.

When analyzing the relationship between GNP and effective taxable self-employment income, it is useful to obtain the ratio of total self-employment income in the U.S. to GNP. This ratio is determined by dividing GNP into net proprietors income as shown in the national income and product accounts. This ratio has declined from 13 percent in 1951 to only 3.9 percent in 1982, or at an average annual rate of 3.8 percent. Much of this drop has been in net farm income which was 5 percent of GNP in 1951 but less than 1 percent in 1982. Obviously there is not much more room for farm income to decrease relative to GNP. Meanwhile nonfarm net proprietors income dropped from 8 percent of GNP in 1951 to 3 percent in 1982. Some of this may be the result of large businesses producing a greater share of GNP now than they did 30 years ago. However, a large portion of this drop is probably the result of the increased formation and incorporation of partnerships, especially in the legal and medical professions. The ratio of net proprietors income to GNP is projected to continue to decrease by a small amount for 10 more years and then to stabilize at from 3.5 percent for alternative I to 3.8 percent for alternative III.

Much net proprietors income is not covered. For example, if the net earnings from self-employment income is less than \$400 in a calendar year, then none of the earnings are covered. The ratio of covered self-employment income to total self-employment income has increased in the past as more types of self-employment income have been covered. It is likely to decrease slightly for a while, however, because farm income, which is covered less than nonfarm income, is likely to become a larger share of total self-employment income. The coverage ratio for self-employment income may seem lower than expected based on the coverage provisions of the Social Security law, but this ratio also includes any discrepancies between how farm income is determined for the national income accounts and how it

is determined for Social Security. This ratio is projected to drop from 81 percent in 1982 to ultimate values in 1993 of 71.3 percent for alternative I and 69.3 percent for alternative III.

Just as with wages, self-employment income above the wage base is not taxable. The ratio of taxable self-employment income to covered self-employment income has fluctuated in the past in a pattern similar to that of the ratio of taxable wages to covered wages. In years when the wage base remained the same the ratio has fallen. The taxable to covered ratio for self-employment income is lower than the corresponding ratio for wages, reflecting the higher average earnings of the self-employed. The ratio of taxable to covered self-employment income has tended to rise gradually even in years when the wage base has increased automatically, reflecting the slower rate of increase in average self-employment income than in average wages. We are projecting this trend to continue until 1993 resulting in the ratio of taxable to covered self-employment income rising from 80 percent in 1982 to ultimate values of 87 percent in alternative I to 84 percent in alternative III.

Prior to 1984, the OASDI tax rate on self-employment income has been about 75 percent of the combined employer-employee OASDI tax rate. This required that taxable self-employment income be multiplied by 75 percent to obtain effective taxable self-employment income. This adjustment is not needed after 1983 since the tax rate on self-employment income will be equal to the combined employer-employee tax rate. Therefore, taxable self-employment income and effective taxable self-employment income are equivalent after 1983.

As a result of all of these assumptions the ratio of effective taxable payroll to GNP is projected to gradually decrease over the long-range future from 44 percent in 1982 to values in 2060 of 42 percent, 39 percent, 37 percent, and 34 percent in alternatives I, II-A, II-B, and III, respectively. The ratio of wages to compensation is assumed to have the most powerful long-range effect. However, the secular downward trend in this ratio is more than offset in the short-range, except in alternative III, by the increased coverage of nonprofit institutions and federal workers and the increase in the tax rate applied to self-employment income.

4. Short-Range GNP and Effective Taxable Payroll

When analyzing and projecting economic experience, we have found the basic concept of potential real GNP a very useful tool. This concept has the important characteristic of providing a smooth baseline series that can be projected more easily than a series that fluctuates widely and against which many economic parameters can be analyzed. Therefore the short-range economic projection begins with a projection of potential real GNP rather than the actual real GNP.

Table 15A shows potential real GNP (in 1972 dollars) as estimated by the Council of Economic Advisors for 1950 through 1982. It is presented as the product of four factors. The first factor is the average full-employment employed labor force during the year, which is labeled "Employment" in the table. This factor is itself the product of the mid-year U.S. population, the average full-employment labor force participation rate during the year, and the complement of the average full-employment unemployment rate during the year. The second factor is the average level of real output per hour paid (or productivity) during the year for the full-employment employed labor force. The third factor is the average number of hours paid per week as measured by the BLS for the total private nonagricultural sector of the economy. The fourth factor is the 52 weeks in a year. For the historical data, the productivity factor was calculated as the residual. As such, this factor represents the average full-employment productivity for the entire U.S. economy as opposed to the published figures for the actual productivity in the business sector.

Tables 15 summarize the projection of actual real GNP by the short-range method. The projected annual percent increases of potential real GNP were calculated as the product of the projected percent increase in the full-employment employed labor force, the assumed percent increase in productivity, the assumed percent decline in average hours paid per week, and a residual factor. This residual factor is the product of 52 weeks per year and an adjustment factor. The adjustment factor is the ratio of the number of covered workers in a year to the average full-employment employed labor force during the year indexed to 1.0 in 1982. This adjustment is necessary to assure consistency with the long-range projection of payroll that will be discussed in the next section. The potential for an inconsistency between GNP and payroll arises because GNP increases in proportion to the increase in the labor force while payroll increases in proportion to the number of covered workers, and in addition, we have fixed the rate of change in productivity, average real wages, and their linkages. We are considering dropping this adjustment factor in the future and allowing one of these rates of change to fluctuate.

The percent increases in the full-employment employed labor force were calculated from our projection of the mid-year U.S. population, full-employment labor force participation rates, and full-employment unemployment rates. The rates of change in productivity and hours paid per week are assumed to move slowly over the first 15 years of the projection from values near the 1982 experience to the ultimate assumptions used in the development of the real wage gain assumption.

Under Alternative I, productivity was assumed to grow from a 1.0 percent increase in 1983 to a 2.7 percent increase in 1992, while the annual decline in hours paid per week was assumed to move from 0.3 percent in 1983 to 0.1 percent in 1986. Since the labor force was projected to grow by 2.1 percent in 1983 and 1.2 percent in 1992, the resulting rate of growth in potential real GNP rose rapidly from 2.8 percent in 1983 to 3.5 percent in 1986 and then slowly to 3.8 percent in 1992.

Under Alternative III, productivity was assumed to increase at about 0.8 percent per year through 1988 and then to grow gradually to 1.8 percent in 1996, while the annual decline in hours paid per week was assumed to move from 0.6 percent in 1983 to 0.4 percent in 1985. Since the labor force was projected to increase by 1.5 percent in 1983 and by 0.9 percent in 1992, the resulting annual increase in potential real GNP was a steady 1.9 percent through 1992.

Similar procedures were used to project potential real GNP for alternatives II-A and II-B, which resulted in an increase of 2.6 percent in 1983, a 3.0 percent increase in 1986, and a 3.3 percent increase in 1992 for alternative II-A, and a fairly steady 2.3 percent increase from 1983 through 1992 for alternative II-B.

For the first few years of the projection, percentage rates of change in actual real GNP were postulated by calendar quarter for each alternative. For 1983 the resulting ratios of actual GNP to potential GNP ranged from 90.9 percent under alternative I to 88.9 percent under alternative III. Since 1950, this ratio has fluctuated between 103.1 percent in 1951 and 90.3 percent in 1982, averaging about 98 percent. When the economy is operating at its deemed full-employment level the actual to potential ratio is by definition 100 percent. Regression analysis of age-sex-specific unemployment rates on the actual to potential ratio shows that ratios of 101.1 percent, 99.1 percent, 98.1 percent, and 96.1 percent are consistent with the ultimate age-sex adjusted unemployment rates of 4.0 percent, 5.0 percent, 5.5 percent, and 6.5 percent assumed for alternatives I, II-A, II-B, and III, respectively. Beginning in 1986, actual real GNP was assumed to grow annually at 4.5 percent, 4.0 percent, 3.0 percent, and 2.7 percent for alternatives I, II-A, II-B, and III, respectively, until the ratio of actual to potential GNP reached its ultimate level. Alternative II-A reached its ultimate level first in 1990, while alternative II-B reached its ultimate level last in 1993. Once the ultimate actual to potential GNP ratio was obtained, actual GNP was assumed to increase at the same rate as potential GNP.

For each alternative, nominal GNP was obtained by multiplying the real GNP by the projected GNP implicit price deflator. The deflator was assumed to increase by the same percent as the CPI, except for the first few years in the projection period.

Because we determined actual GNP as a percentage of potential GNP, it was only necessary for us to develop full-employment figures for employment, productivity, and hours per week. Tables 16 show the employment, productivity, and hours per week that are consistent with the actual GNP. The actual employment was obtained by first deriving the actual unemployment rates from the actual to potential ratio. Then labor force participation rates consistent with actual unemployment rates were calculated. Finally, the actual participation rates and unemployment rates were applied to the July 1 U.S. population to determine the actual level of employment. Hours paid per week were as measured by the BLS for the

total private nonagricultural sector of the economy. It should be recalled that this measure of actual hours per week was also used, for simplicity, in the calculation of potential GNP. Productivity was calculated as the residual. As such, it represents the average actual productivity for the entire U.S. economy and should properly reflect the cyclical behavior of productivity.

During the short-range period effective taxable payroll is estimated from GNP by a much detailed method that determines the interrelationships between the two. The projection of these interrelationships and the calculation of effective taxable payroll are performed under the direction of Mr. Kenneth G. Sander of the Office of Research and Statistics. The ratios of effective taxable payroll to GNP in 1983 through 1992 shown in Tables 14A through 14E summarize the results of Mr. Sander's projection.

5. Long-Range Effective Taxable Payroll and GNP

Tables 17A through 17E summarize the long-range method of calculating effective taxable payroll. The values shown in these tables from 1983 through 1992 are generated from the short-range economic model of Mr. Sander. After 1992 the taxable payroll for employers, employees, and the self-employed are calculated separately by multiplying the previous year's payroll by the percentage increase in the number of covered workers and by the percentage increase in average covered wages. Each of these projected payrolls are multiplied by the appropriate tax rate to obtain total taxes. The total taxes divided by the combined employer-employee tax rate yields effective taxable payroll, and total outgo divided by effective taxable payroll yields the projected cost rates. GNP can be obtained by dividing effective taxable payroll by the ratios of effective taxable payroll to GNP shown in Tables 14A through 14E.

D. RESULTS

1. Effective Taxable Payroll

As shown in Tables 17A through 17E, the rate of growth in payroll decreases steadily from the mid-1980's to the year 2020 under all four alternatives. Since the increase in average covered wages is assumed to be constant after 1993 in all alternatives, this deceleration is the result of a slow down in the rate of growth in the number of covered workers. This slow down begins in the mid-1980's because of the decreasing number of new entrants into the labor force, which is a result of the declines in fertility rates between 1957 and the present. However, the slow down is especially pronounced shortly after the turn of the century when persons born during the high fertility years from 1946 through the mid-1960's begin to leave the labor force and retire. In 2020, the number of covered workers grows by only 0.2 percent in alternative I, while it actually decreases by 0.5 percent in alternative III. The difference in the rate of growth in the number of covered workers among the alternatives results largely from the greater number of persons entering the labor force in alternative I, which assumes a 2.3 total fertility rate, than in alternative III, which assumes a 1.6 total fertility rate.

The resulting increase in payroll in 2020 is 4.7 percent, 4.9 percent, 5.4 percent, and 5.5 percent in alternatives I, II-A, II-B, and III, respectively. After adjusting for the increase in the CPI the corresponding figures are 2.7 percent, 1.9 percent, 1.4 percent, and 0.5 percent.

After 2020 the rate of increase in payroll remains fairly stable under alternative III and increases slightly under the other alternatives, in all cases following the path in the rate of growth of covered workers.

2. GNP, Effective Taxable Payroll, and Their Linkages

Tables 18 summarize for each alternative the GNP (which is consistent with the GNP shown Tables 16), the effective taxable payroll (which is consistent with the payroll shown in Tables 17), and several intermediate values, including total employee compensation, wages, covered wages, total self-employment income and covered self-employment income. The GNP in the year 2060 varies from \$392 trillion in alternative III to \$198 trillion in alternative I, which yield average annual increases from 1982 to 2060 of 6.4 percent and 5.5 percent, respectively. In 1972 dollars, the GNP in the year 2060 varies from \$19 trillion in alternative I to \$4 trillion in alternative III, which yield average annual increases from 1982 to 2060 of 3.4 percent and 1.3 percent, respectively.
